ABSTRACT

We have carried out sensitive OH Zeeman observations of the absorption lines produced in interstellar dust clouds toward 3C 133, 3C 123, and W51. Conservative (3σ) upper limits to the magnetic field strengths at each position are 15, 25, and 30 microgauss respectively.

THE LOCAL INTERSTELLAR MEDIUM

RICHARD M. CRUTCHER

Astronomy Department, University of Illinois; and
Radio Astronomy Laboratory, University of California, Berkeley

Received 1980 September 8; accepted 1981 July 16

ABSTRACT

Analysis of the velocities of optical interstellar lines shows that the Sun is immersed in a coherently moving local interstellar medium whose velocity vector agrees with that of the interstellar wind observed through backscatter of solar H Ly α and He λ 584 photons. The local interstellar medium consists of both cool clouds and warm intercloud medium gas, has a mass of perhaps $\sim 30 M_{\odot}$, does not have severe depletion of trace elements from the gas phase, and appears to be material which has been shocked and accelerated by stellar winds and supernovae associated with the Sco-Oph OB association.

The magnetic field of the NGC 2024 molecular cloud: detection of OH line Zeeman splitting

Richard M. Crutcher^{1,2} and Ilya Kazès¹

¹ Department de Radioastronomie, Observatoire de Paris-Meudon, F-92195 Meudon, France

Received June 3, accepted July 14, 1983

Summary

Zeeman splitting of the main lines of OH in absorption has been detected for the first time. The derived magnetic field for a clump in the NGC 2024 molecular cloud is -38 ± 1 microgauss.

Key words: magnetic fields — interstellar molecular clouds — Zeeman effect

The antenna feed is a horn (Pippard, 1946) with orthogonal dipoles in a circular waveguide. A noise diode signal may be injected into the horn for calibration. The horizontally and vertically orientated linear polarizations are coupled to unbalanced transmission circuits by folded baluns (Jasik, 1961); the polarization isolation is measured to be in excess of 40 dB. After amplification by cooled paramps or PNP's, the linearly polarized signals are combined with the appropriate phases in a hybrid to produce circularly polarized

Fig. 1. Spectra of the 367 (top) and 365 (bottom) OH lines toward NGC 2024 (RA/DEC: 1950.01 07 39 1423 / -31° 55' 57"). The weakest line is the second quartet component used for Zeeman analysis.

The absorption scale in all figures is the same and is given in km^{-2} relative to the LSR. The ordinate scale in % antenna temperature is shown except that displacements of zero have been made in most figures.

MEASUREMENT OF MAGNETIC FIELD STRENGTH IN THE DARK CLOUD BARNARD 1
 A. A. GOODMAN,^{1,2} B. M. CHURCH,² C. HEILES,⁴ P. C. MYERS,² AND T. H. TROLAND³

ABSTRACT

We report the detection of a $-27 \pm 4 \mu\text{G}$ magnetic field in the molecular cloud Barnard 1 (B1), via observations of the Zeeman effect in the 1665 and 1667 MHz lines of OH at the Arecibo 305 m telescope. The region of OH emission is $1.5 \times 10^4 \text{ pc}^2$ in area, 0.3 pc in line width, and has mean column density $6 \times 10^{21} \text{ cm}^{-2}$. Detection of the Zeeman effect provides one of the first field strength measurements directly relevant to a dense part of a region of low-mass star formation. Substitution of the OH line width, size, and column density information into models based on comparable magnetic, kinetic, and gravitational energy densities, the cloud magnetic field strength is estimated to be $\sim 25 \mu\text{G}$, in agreement with the measured value. The data are consistent with larger ($\sim 3 \text{ pc}$; ^{13}CO) and smaller ($\sim 0.2 \text{ pc}$; Zeeman) measurements. The field strength is consistent with equipartition with the gas, a range which may be insignificant compared to measurement error. The observed field strength is also consistent with a constant-mass equilibrium model of cloud evolution. B1 has an embedded low-luminosity ($3 L_{\odot}$) IRAS source and is one of many similar objects in the Perseus complex which may thus prove useful for studies of the early stages of star formation.

OPTICAL POLARIZATION MAPS OF STAR-FORMING REGIONS PERSEUS, TAURUS,
 AND ORION

ABSTRACT

We present new optical polarimetry observations of the star-forming regions L1506 in Taurus, L1755 in Ophiuchus, and the Perseus complex. The polarization vectors in the Perseus complex are oriented at about 25° to the projected axis of the dark cloud, but are oriented at about 25° to the projected axis of the Taurus cloud complex. In the L1755 region, the individual polarization vectors are remarkably well aligned with each other and with the projected elongation of the cloud. As in Taurus, this observed alignment may be understood in terms of a model in which the magnetic field is oriented perpendicular to the filamentary structure. In Perseus, no such alignment is observed. We propose that the observed alignment in Perseus is due to the fact that the dark filaments are located in more than one cloud complex along the line of sight of Perseus. Molecular spectral line observations, which show gas in two distinct velocity ranges, support this hypothesis.

The distribution of polarization vectors in the Perseus complex is consistent with a model in which the magnetic field is oriented perpendicular to the filamentary structure. This model is consistent with the observed alignment of the polarization vectors with the projected elongation of the cloud.

ABSTRACT

We present results of $\lambda 1.3$ mm dust-polarization observations toward 16 nearby, low-mass protostars, mapped with $\sim 2''.5$ resolution at CARMA. The results show that magnetic fields in protostellar cores on scales of ~ 1000 AU are not tightly aligned with outflows from the protostars. Rather, the data are consistent with scenarios where outflows and magnetic fields are preferentially misaligned (perpendicular), or where they are randomly aligned. If one assumes that outflows emerge along the rotation axes of circumstellar disks, and that the outflows have not disrupted the fields in the surrounding material, then our results imply that the disks are not aligned with the fields in the cores from which they formed.

XXXII. The relative orientation between the magnetic field and structures traced by interstellar dust

Planck Collaboration: R. Adam⁰⁸, P. A. R. Ade⁷⁹, N. Aghanim⁵⁴, M. L. R. Alves⁵⁴, M. Arnaud⁶⁶, D. Arzoumanian³⁶, M. Ashdown^{63,6}, . . .

ABSTRACT

The role of the magnetic field in the formation of the filamentary structures observed in the interstellar medium (ISM) is a debated topic owing to the paucity of relevant observations needed to test existing models. The *Planck* all-sky maps of linearly polarized emission from dust at 353 GHz provide the required combination of imaging and statistics to study the correlation between the structures of the Galactic magnetic field and of interstellar matter over the whole sky, both in the diffuse ISM and in molecular clouds. The data reveal that structures, or ridges, in the intensity map have counterparts in the Stokes Q and/or U maps. We focus our study on structures at intermediate and high Galactic latitudes, which cover two orders of magnitude in column density, from 10^{20} to 10^{22} cm⁻². We measure the magnetic field orientation on the plane of the sky from

aligned with the magnetic field measured on the structures. This statistical trend becomes more striking for increasing polarization fraction and decreasing column density. There is no alignment for the highest column density ridges. We interpret the increase in alignment with polarization

aligned with the magnetic field measured on the structures. This statistical trend becomes more striking for increasing polarization fraction and decreasing column density. There is no alignment for the highest column density ridges. We interpret the increase in alignment with polarization fraction as a consequence of projection effects. We present maps to show that the decrease in alignment for high column density is not due to a loss of correlation between the distribution of matter and the geometry of the magnetic field. In molecular complexes, we also observe structures perpendicular to the magnetic field, which, statistically, cannot be accounted for by projection effects. This first statistical study of the relative orientation between the matter structures and the magnetic field in the ISM points out that, at the angular scales probed by *Planck*, the field geometry projected on the plane of the sky is correlated with the distribution of matter. In the diffuse ISM, the structures of matter are usually aligned with the magnetic field, while perpendicular structures appear in molecular clouds. We discuss our results in the context of models and MHD simulations, which attempt to describe the respective roles of turbulence, magnetic field, and self-gravity in the formation of structures in the magnetized ISM.

Key words. ISM: clouds – ISM: magnetic fields – ISM: structure – magnetohydrodynamics (MHD) – polarization – turbulence

1990

A number of studies, using the polarization of background starlight caused by dichroic absorption, have targeted filaments in dark clouds (e.g. Goodman et al. 1990, 1995; Pereyra & Magalhães 2004; Alves et al. 2008; Chapman et al. 2011; Cashman & Clemens 2014), and in the diffuse ISM at lower column densities (McClure-Griffiths et al. 2006; Clark et al. 2014).

MAGNETIC FIELDS IN INTERSTELLAR CLOUDS FROM ZEEMAN OBSERVATIONS: INFERENCE OF TOTAL FIELD STRENGTHS BY BAYESIAN ANALYSIS

ABSTRACT

The only direct measurements of interstellar magnetic field strengths depend on the Zeeman effect, which samples many fields are so weak that the mass/flux ratio in many clouds must be significantly supercritical. A two-thirds power law comes from isotropic contraction of gas too weakly magnetized for the magnetic field to affect the morphology of the collapse. On the other hand, our study does not rule out some clouds having strong magnetic fields with critical mass/flux ratios.

density. This suggests that diffuse clouds are assembled by flows along magnetic field lines, which would increase the density but not the magnetic field strength. We further find strong evidence for B in molecular clouds being randomly distributed between very small values and a maximum that scales with volume density n as $B \propto n^{0.65}$ for $n > 300 \text{ cm}^{-3}$, with an uncertainty at the 50% level in the power-law exponent of about ± 0.05 . This break-point density could be interpreted as the average density at which parsec-scale clouds become self-gravitating. Both the uniform PDF of total field strengths and the scaling with density suggest that magnetic fields in molecular clouds are often too weak to dominate the star formation process. The stochasticity of the total field strength B implies that many fields are so weak that the mass/flux ratio in many clouds must be significantly supercritical. A two-thirds power law comes from isotropic contraction of gas too weakly magnetized for the magnetic field to affect the morphology of the collapse. On the other hand, our study does not rule out some clouds having strong magnetic fields with critical mass/flux ratios.

A MODERN LOOK AT 'INTERSTELLAR CLOUDS'

CARL HEILES

University of California, Berkeley, Calif., U.S.A.

Abstract. We compare past and present modes of investigation of the structure of the interstellar gas. Many aspects of the interstellar cloud model are invalid.

Interstellar optical absorption lines and HI 21-cm emission lines show a number of very large aggregates with properties similar to those of 'cloud complexes'. At nonzero velocities especially for $b < 0^\circ$, exist optical lines which have no HI counterparts. These are almost certainly produced in low-density gas clouds; perhaps the intercloud medium is itself cloudy.

Maps of HI column density taken over large velocity ranges do not reveal much small-scale structure. This fact cannot easily be reconciled with the statistical analyses of interstellar reddening. The maps do reveal large, coherent gas structures which are often filamentary in shape and at least sometimes aligned parallel to the interstellar magnetic field.

Maps of HI column density over small velocity ranges show much small-scale structure, often filamentary in shape. The filaments are almost universally oriented parallel to the interstellar magnetic field and have Doppler velocity gradients along their lengths. In one area the geometry of the field and gas almost exclusively suggests Alfvén-type motions.

The Carlverse, 1974

A MODERN LOOK AT 'INTERSTELLAR CLOUDS'

CARL HEILES

University of California, Berkeley, Calif., U.S.A.

Abstract. We compare past and present modes of investigation of the structure of the interstellar gas.

Until recently, insufficient data have been available to make such a discussion. We will find that some aspects of the cloud model remain valid. Other aspects, especially the assumptions concerning randomness, are incorrect. Much of the observable gas is affected by the interstellar magnetic field and/or huge explosions. Many large aggregates contain hierarchical structure with non-random shapes and velocities. Outside these aggregates, the gas is often distributed in long, delicate, interconnected filaments rather than clouds.

THE SKELETON OF THE MILKY WAY

CATHERINE ZUCKER¹, CARA BATTERSBY², AND ALYSSA GOODMAN²

¹Astronomy Department, University of Virginia, Charlottesville, VA 22904, USA, catherine.zucker@virginia.edu

²Harvard-Smithsonian Center for Astrophysics, Cambridge, MA 02138, USA

Received 2015 June 27; accepted 2015 September 27; published 2015 May 10

ABSTRACT

Recently, Goodman et al. argued that the very long, very thin infrared dark cloud “Nessie” lies directly in the Galactic midplane and runs along the Scutum–Centaurus Arm in position–position–velocity (p – p – v) space as traced by lower-density CO and higher-density NH_3 gas. Nessie was presented as the first “bone” of the Milky Way, an extraordinarily long, thin, high-contrast filament that can be used to map our Galaxy’s “skeleton.” Here we present evidence for additional bones in the Milky Way, arguing that Nessie is not a curiosity but one of several filaments that could potentially trace Galactic structure. Our 10 bone candidates are all long, filamentary, mid-infrared extinction features that lie parallel to, and no more than 20 pc from, the physical Galactic mid-plane. We use CO, N_2H^+ , HCO^+ , and NH_3 radial velocity data to establish the three-dimensional location of the candidates in p – p – v space. Of the 10 candidates, 6 also have a projected aspect ratio of $\geq 50:1$; run along, or extremely close to, the Scutum–Centaurus Arm in p – p – v space; and exhibit no abrupt shifts in velocity. The evidence presented here suggests that these candidates mark the locations of significant spiral features, with the bone called filament 5 (“BC_18.88-0.09”) being a close analog to Nessie in the northern sky. As molecular spectral-line and extinction maps cover more of the sky at increasing resolution and sensitivity, it should be possible to find more bones in future studies.

Key words: Galaxy: kinematics and dynamics – Galaxy: structure – ISM: clouds

2.3. Establishing “Bone” Criteria

After narrowing down our list to 10 filaments with kinematic structure consistent with existing spiral arm models, we develop a set of criteria for an object to be called a “bone”:

1. Largely continuous mid-infrared extinction feature
2. Parallel to the Galactic plane, to within 30°
3. Within 20 pc of the physical Galactic mid-plane, assuming a flat galaxy
4. Within 10 km s^{-1} of the global-log spiral fit to any Milky Way arm
5. No abrupt shifts in velocity (of more than 3 km s^{-1} per 10 pc) within extinction feature
6. Projected aspect ratio $\geq 50:1$.

Figure 3. Distributions of length, radius, aspect ratio, and mass for the 10 bone candidates, based on data from Table 2.

Figure 1. Results of performing a slice extraction along the filamentary extinction feature of our strongest bone candidate, filament 5. The top panel shows a *Spitzer*-GLIMPSE 8 μm image of filament 5, and the red trace indicates the curve (coincident with the extinction feature) along which a *p-v* slice was extracted. The bottom panel shows the *p-v* slice, with the red boxed region indicating the emission corresponding to filament 5.

Figure 2. Position-velocity summary of bone candidates and spiral arm models. Blue background shows ¹²CO emission from Dame et al. (2001), integrated between 1° < *b* < 1°. Black dots show measurements of BGPS-, HOPS-, MALT90-, and GRS-determined velocities, with particular candidate filaments identified by number (see Table 1 for further identification), or, in the case of Nessie, by name. Lines of varying color show predicted *p-v* spiral arm traces from the literature (see text for references).

2014 Simulation

"Now"

B5 (Chen, Goodman & Pienda)

PROBLEM 1

On what scale(s) does filamentary structure matter, and when, in the end-game of star-formation?

PHD 1

For synthetic observations best "matching" molecular line & dust data, determine from whence and when bulk of mass gets to forming cores & stars. Particular focus on timing.

with: Mészáros, Glover, Smith, Fuller, Caselli, André, Alves, Lombardi, Hacar, Tafall, related to work of 30 year Harvard grad student P. Clark

“Connections”: What if filaments continue across “core” boundaries?

blue =VLA ammonia (high-density gas); green=GBT ammonia (lower-res high-density gas); red=Herschel 250 micron continuum (dust)

ABSTRACT

The physical properties of molecular clouds are often measured using spectral-line observations, which provide the only probes of the clouds' velocity structure. It is hard, though, to assess whether and to what extent intensity features in position–position–velocity (PPV) space correspond to “real” density structures in position–position–position (PPP) space. In this paper, we create synthetic molecular cloud spectral-line maps of simulated molecular clouds, and present a new technique for measuring the reality of individual PPV structures. Using a dendrogram algorithm, we identify hierarchical structures in both PPP and PPV space. Our procedure projects density structures identified in PPP space into corresponding intensity structures in PPV space and then measures the geometric overlap of the projected structures with structures identified from the synthetic observation. The fractional overlap between a PPP and PPV structure quantifies how well the synthetic observation recovers information about the three-dimensional structure. Applying this machinery to a set of synthetic observations of CO isotopes, we measure how well spectral-line measurements recover mass, size, velocity dispersion, and virial parameter for a simulated star-forming region. By disabling various steps of our analysis, we investigate how much opacity, chemistry, and gravity affect measurements of physical properties extracted from PPV cubes. For the simulations used here, which offer a decent, but not perfect, match to the properties of a star-forming region like Perseus, our results suggest that superposition induces a $\sim 40\%$ uncertainty in masses, sizes, and velocity dispersions derived from ^{13}CO ($J = 1-0$). As would be expected, superposition and confusion is worst in regions where the filling factor of emitting material is large. The virial parameter is most affected by superposition, such that estimates of the virial parameter derived from PPV and PPP information typically disagree by a factor of ~ 2 . This uncertainty makes it particularly difficult to judge whether gravitational or kinetic energy dominate a given region, since the majority of virial parameter measurements fall within a factor of two of the equipartition level $\alpha \sim 2$.

ABSTRACT
The physical properties of molecular clouds are often measured using spectral-line observations, which provide the only probes of the clouds' velocity structure. It is hard, though, to assess whether and to what extent intensity features in position-position-velocity (PPV) space correspond to "real" density structures in position-position-position (PPP) space. In this paper, we create synthetic molecular cloud spectral-line maps of simulated molecular clouds, and present a new technique for measuring the reality of individual PPV structures. Using a dendrogram algorithm, we identify hierarchical structures in both PPP and PPV space. Our procedure projects density structures identified in PPP space into corresponding intensity structures in PPV space and then measures the geometric overlap of the projected structures with structures identified from the synthetic observation. The fractional overlap between a PPP and PPV structure quantifies how well the synthetic observation recovers information about the three-dimensional structure. Applying this machinery to a set of synthetic observations of CO isotopes, we measure how well spectral-line measurements recover mass, size, velocity dispersion, and virial parameter for a simulated star-forming region. By disabling various steps of our analysis, we investigate how much opacity, chemistry, and gravity affect measurements of physical properties extracted from PPV cubes. For the simulations used here, which offer a decent, but not perfect, match to the properties of a star-forming region like Perseus, our results suggest that superposition induces a ~40% uncertainty in masses, sizes, and velocity dispersions derived from ¹³CO ($J=1-0$). As would be expected, superposition and confusion is worst in regions where the filling factor of emitting material is large. The virial parameter is most affected by superposition, such that estimates of the virial parameter derived from PPV and PPP information typically disagree by a factor of ~2. This uncertainty makes it particularly difficult to judge whether gravitational or kinetic energy dominate a given region, since the majority of virial parameter measurements fall within a factor of two of the equipartition level $\alpha \sim 2$.

ABSTRACT

The all-Galaxy CO survey of Dame et al. is by far the most uniform, large-scale Galactic CO survey. Using a dendrogram-based decomposition of this survey, we present a catalog of 1064 massive molecular clouds throughout the Galactic plane. This catalog contains 2.5×10^8 solar masses, or $25_{-5.8}^{+10.7}\%$ of the Milky Way’s estimated H₂ mass. We track clouds in some spiral arms through multiple quadrants. The power index of Larson’s first law, the size–linewidth relation, is consistent with 0.5 in all regions—possibly due to an observational bias—but clouds in the inner Galaxy systematically have significantly (~30%) higher linewidths at a given size, indicating that their linewidths are set in part by the Galactic environment. The mass functions of clouds in the inner Galaxy versus the outer Galaxy are both qualitatively and quantitatively distinct. The inner Galaxy mass spectrum is best described by a truncated power law with a power index of $\gamma = -1.6 \pm 0.1$ and an upper truncation mass of $M_0 = (1.0 \pm 0.2) \times 10^7 M_\odot$, while the outer Galaxy mass spectrum is better described by a non-truncating power law with $\gamma = -2.2 \pm 0.1$ and an upper mass of $M_0 = (1.5 \pm 0.5) \times 10^6 M_\odot$, indicating that the inner Galaxy is able to form and host substantially more massive GMCs than the outer Galaxy. Additionally, we have simulated how the Milky Way would appear in CO from extragalactic perspectives, for comparison with CO maps of other galaxies.

alyssa, you must be dreaming. Healpix in 1981? even fits (i dunno about fits...). i don't recall how i made (i assume it was me, not dave) that contour plot, but back in those days the only way i can imagine was to use a Calcomp plotter. That's a pen-and-ink plotter that used paper 2 or 3 feet wide on a roll so the length could be arbitrarily long.

like, the students in my just-given radio astronomy lab class make 21-cm line images of large peices of the sky from their own data with our lab 3.5 m dish and change contrast, etc at will, on our modern-day monitors. one of them dug up some of my old papers with such images that i made in yesteryear. i tell the students what i had to go through to make such images--they were made with a computer controlled laser scanning back and forth on a 3 x 4 inch (i think) glass photographic plate and I would do a set of four on each plate to get four 35 mm slides. i'd do the ones in each set with different laser intensities and stretches, and hope that i'd successfully develop the plates and one would be suitable. and, also, that i'd be succdessful in using a glass cutter to get the four slids from the larger plate without braking anything. and then there were the color images, with color representing velocity, made with ed jenkins. for that we used a modified computer-controlled laseer scanner, originally made for use in magazine publishing, that worked on 12x18 negative plastic, and direct-contact it to make images on photogaphic paper.

anyway, i have no idea where the original files might be--and even if i did, you'd have a tough time finding a Calcomp plotter to go with them!

A gift to Carl from Alyssa, Josh, Greg Green, Doug Finkbeiner & Catherine Zucker.
